Abstract

In order to predict accurately how elevated atmospheric CO2 concentrations will affect the global carbon cycle, it is necessary to know how trees respond to increasing CO2 concentrations. In this paper, we examine the response over the period AD 1895–1994 of three tree species growing across northern Europe to increases in atmospheric CO2 concentrations using parameters derived from stable carbon isotope ratios of trunk cellulose. Using the isotope data we calculate values of intrinsic water-use efficiency (IWUE) and intercellular CO2 concentrations in the leaf (ci). Our results show that trees have responded to higher levels of atmospheric CO2 by increasing IWUE whilst generally maintaining constant ci values. However, the IWUE of most of the trees in this study has not continued to rise in line with increasing atmospheric CO2. This behaviour has implications for estimations of future terrestrial carbon storage.

1. Introduction

The annual growth rings of trees provide a uniquely valuable source of past environmental information. They have certain advantages over other proxy sources of environmental data, such as ice-cores from polar and mountainous regions, lake sediments and speleothems, in that tree rings can be dated unambiguously to precise years and that trees grow in a wide range of terrestrial environments. Ring width and latewood densities have been successfully used for climatic reconstruction in areas where tree growth is influenced by one predominant factor such as summer temperature (Briffa et al., 1995) or precipitation (LaMarche, 1974). In temperate regions, tree growth is usually influenced by several factors, and the relationship between ring widths and climatic parameters is weaker. In these regions the ratios of stable isotopes in tree rings have been shown to correlate with climatic parameters such as growing season temperature, relative humidity and precipitation (see Switsur and Waterhouse, 1998, and references therein).

We have previously shown that trees growing in sites in eastern England (Robertson et al., 1997a; Hemming et al., 1998) and southwest Finland (Robertson et al., 1997b) record climatic variables (in particular growing season temperature and relative humidity) in the carbon isotope ratios of α-cellulose extracted from annual growth rings. In this paper, we reassess these carbon stable isotope records, which extend over most of the last century, in order to gain insight into trees’ response...
to increasing atmospheric carbon dioxide concentrations and how this response varies with site conditions and atmospheric CO$_2$ concentrations.

Plants respond to increasing levels of atmospheric carbon dioxide in several ways. Experimental results (Morison, 1993; Polley et al., 1993; Picon et al., 1996) and theoretical models (Beerling, 1994; Thornley and Cannell, 1996; Cao and Woodward, 1998) indicate that plants are able to increase their water-use efficiency (WUE) as CO$_2$ levels rise. Short-term experimental results from studies of plants in growth chambers, however, may not reliably predict the behaviour of mature trees growing in their natural environment, as trees are able to adjust their physiological response over time to gradually increasing CO$_2$ concentrations. As shown below, intrinsic water-use efficiency (IWUE) can be calculated from values of stable carbon isotope ratios from tree organic matter, and these values can give insight into how naturally growing trees respond, or have responded, to increasing atmospheric CO$_2$ concentrations. Studies of this nature have been carried out on freely growing trees in the USA (Marshall and Monserud, 1996; (Feng, 1998, 1999; Tang et al., 1999), Quebec (Watmough et al., 2001), Tasmania (Francey and Farquhar, 1982) and France (Bert et al., 1997; Duquesnay et al., 1998) and have revealed that trees vary in their responses to increasing atmospheric CO$_2$ concentrations.

Isotopic discrimination ($\Delta^{13}C$) between carbon of atmospheric CO$_2$ and plant carbon for C$_3$ plants is defined in Eq. (1):

$$\Delta^{13}C = (\delta^{13}C_a - \delta^{13}C_p)/(1 + \delta^{13}C_p/1000),$$

(1)

where $\delta^{13}C_a$ and $\delta^{13}C_p$ are the isotopic ratios of carbon ($^{13}C/^12C$) in atmospheric CO$_2$ and plant material respectively expressed in parts per mille (‰) relative to VPDB. $\Delta^{13}C$ is related to the ratio between the intercellular ($c_i$) and atmospheric ($c_a$) concentrations (mole fractions) of CO$_2$ as expressed by Eq. (2) (Farquhar et al., 1989):

$$\Delta^{13}C = a + (b - a)c_i/c_a,$$

(2)

where $a$ is the discrimination due to diffusion of CO$_2$ in air (4.4‰) and $b$ is the discrimination during carboxylation for C$_3$ plants (28‰) (Brugnoli et al., 1998). IWUE is defined as the ratio of assimilation rate ($A$) for uptake of CO$_2$ to leaf conductance to water vapour ($g_w$) (Ehleringer, 1993). Since $g_w = 1.6g_c$ ($g_c$ is the stomatal conductance to CO$_2$), and $A = g_c(c_i - c_a)$, it is possible to calculate values of IWUE from values of $\Delta^{13}C$ (Eq. (3)):

$$\text{IWUE} = c_a(b - \Delta^{13}C)/1.6(b - a).$$

(3)

IWUE is equal to instantaneous water-use efficiency (instWUE) (determined by leaf gas exchange) multiplied by the difference in water vapour mole fraction between leaf and atmosphere. Units of IWUE are those of CO$_2$ mole fraction (µmol mol$^{-1}$); those of instWUE are µmol CO$_2$/mol H$_2$O. The advantage of IWUE over instWUE is that the former allows assessment of the role of biological components in determining water–carbon exchange relationships independently of changing atmospheric conditions (Ehleringer, 1993).

2. Sites and methods

Values of IWUE were calculated for trees of three species: pedunculate oak (Quercus robur L.), common beech (Fagus sylvatica L.) and Scots pine (Pinus sylvestris L.). The trees were from three geographical regions in northern Europe: northwest Norfolk, south Bedfordshire (both in eastern England) and southwest Finland (Table 1). In two of the regions (northwest Norfolk and southwest Finland), sites with differing hydrological regimes and soil types were selected; these are classed as ‘dry’ and ‘wet’ as appropriate. In northwest Norfolk, the dry site (NORD) is on freely draining lower Cretaceous sands, while the wet site (NORW) occupies the often waterlogged floodplain of the River Babingley, some 3 km south of the dry site. The dry site in southwest Finland (FIND) sits astride a rock-strewn area of freely draining glacial drift; the nearby wet site (FINW) on lower ground is underlain by argillaceous marine clays and silts. Confirmation of the difference in hydrologies between the two Finnish sites is provided by soil moisture analysis (Barker, 2000), which showed that the soil moisture content at FINW was 50% greater than that at FIND down to a depth of 0.5 m. The differences in hydrology between sites enabled us to investigate the effects of changing water availability on tree response to increasing $c_a$ under the same local climatic conditions. Oaks were sampled in all regions, whereas Scots pine and beech were sampled in south Bedfordshire only; thus we can compare variations of one species across geographical regions and the behaviour of three species in one location. All the trees selected were over 150 years old. In order to minimize complications arising from the juvenile effect, which produces more negative values of $\delta^{13}C$ in wood produced during the first few decades of growth (Freyer and Belacy, 1983) as a result of assimilating respired CO$_2$ depleted in $^{13}C$ (Keeling, 1961) or reduced light levels lower in the canopy (Heaton, 1999), we sampled the most recent 100 years of annual rings.

We measured the carbon isotope ratios of samples of $\omega$-cellulose ($^{13}C_{cell}$) extracted from the latewood of annual rings for the period 1895–1994 for both oak and Scots pine as previously described (Loader et al., 1997; Robertson et al., 1997a, b; Hemming et al., 1998), and hence calculated values of IWUE correspond to the period of latewood formation for these species. As the
beech is a diffuse porous species, it was not possible to distinguish and separate latewood from earlywood unambiguously from each growth ring, and therefore the whole ring was sampled. For each species at each site, annual values of $\delta^{13}C_{\text{cell}}$ were calculated as an average for the number of trees samples (Table 1) and annual values of IWUE were calculated from these according to Eq. (3). Values of $\delta^{13}C_a$ and $c_i$ for each year were determined as previously described (see Hemming et al., 1998 for details) using ice-core data from Antarctica and measured atmospheric data from Antarctica and Europe.

A number of possible sources of error needs to be considered. Values of $\delta^{13}C_{\text{cell}}$ in Eqs. (2) and (3) ought, strictly speaking, to refer to initial photosynthate in the leaf, (Heaton, 1999) and not cellulose in the trunk. Using $\delta^{13}C_{\text{cell}}$ in place of $\delta^{13}C_p$ may therefore introduce some bias into calculated values of IWUE and $c_i$. Wood cellulose is generally enriched in $^{13}C$ relative to leaf cellulose, with an enrichment value of 3–4‰ reported for juniper (J. monosperma) from Arizona (Leavitt and Long, 1982), although the degree of enrichment may be dependent upon species (Schleser, 1990; White et al., 1993). Leaf tissue is formed early in the growing season, when values of $c_i/c_a$ values are relatively high, resulting in correspondingly low values of $\delta^{13}C$ (Francy et al. 1985; Jäggi et al., 2002). Feng (1998, 1999) argues that wood in the trunk formed later in the season originates from exported carbohydrate formed in mature leaves within which $c_i/c_a$ attains lower values; hence $\delta^{13}C$ values of leaf photosynthate are closer to those of trunk wood, the $\delta^{13}C$ value of which can therefore legitimately be used for calculation of IWUE. Moreover, with the exception of beech, we measure $\delta^{13}C$ values in the latewood only, hence differences in leaf and wood $\delta^{13}C$ should be minimized further. Even if using values of $\delta^{13}C_{\text{cell}}$ to calculate IWUE does produce a bias in the calculated values, it does not alter their temporal trends, which form the main subject of this paper.

Another factor that should be considered is that the carbon dioxide sampled by trees may not have values of $\delta^{13}C$ that are the same as that of the general atmosphere ($\delta^{13}C_a$) owing to mixing of respired CO$_2$ into the local atmosphere sampled by the tree. This effect is likely to be much more important for young trees growing below the canopy and is minimized in this study by exclusion of at least the first 50 years of growth. Also, trees from the NORD and BEDS sites are growing in open environments, and hence likely to be sampling CO$_2$ with $\delta^{13}C$ value close to $\delta^{13}C_a$; however, this may not be the case for the more wooded sites of FIND, FINW and NORW.

<sup>a</sup> N is no. of trees used for isotope measurements.

<sup>b</sup> The terms ‘dry’ and ‘wet’ were assigned on the basis of the hydrological regimes at each site (soil type and drainage) and not on precipitation (see Robertson et al., 1997a,b for details).

### 3. Results and discussion

Annual values of IWUE for each species at each site (calculated from Eqs. (1) and (3)) are shown in Fig. 1. The high-frequency fluctuations, which are similar for trees from the same site, reflect the high correlation between $\delta^{13}C_{\text{cell}}$ and local climatic parameters (e.g. summer temperature, humidity and precipitation) and the effects of climatic conditions on isotopic discrimination (for full details of these climatic relationships see Robertson et al., 1997a,b; Hemming et al., 1998). It is evident from Fig. 1 that all species at all the sites show a long-term increase in their values of IWUE during the past century.

The main cause of this common behaviour is likely to be the increase in atmospheric CO$_2$ concentration, although changing parameters that can influence IWUE through their effects on stomatal aperture, and hence $\Delta^{13}C$, might also play a part. Of the three meteorological parameters available at all geographical locations in this study (temperature, precipitation and relative humidity) it is relative humidity that has shown the most significant change in two of regions: Norfolk and southwest Finland (Figs. 2a and c); however, there has been no significant decrease in relative humidity in Bedfordshire (Fig. 2b). Previous analysis has shown that relative humidity or the derived vapour pressure deficit also has the strongest relationship with carbon isotope ratios in all three regions (Robertson et al., 1997a,b; Hemming et al., 1998); therefore the possible effect of this parameter alone on values of IWUE are explored here. Average changes in relative humidity are very similar in Norfolk and southwest Finland: 7% (since 1920) and 8% (since 1895), respectively. The isotopic discrimination/relative humidity coefficients (obtained by linear regression analysis) are also very similar: 0.065‰/% for Norfolk and 0.074‰/% for Finland.
Although there is much uncertainty involved in this analysis, the observed changes in relative humidity might therefore be responsible for an increase in $\Delta^{13}$C of about 0.5% at the two sites, through its effects on stomatal aperture (Beerling, 1996). This would lead to an increase in IWUE (Eq. (3)) of about 4–5 μmol mol$^{-1}$ over the period of study for trees from these two sites. Other factors may also play a role; for example, recent studies (Keiller and Holmes, 2001) have demonstrated that increased UV-B has profound effects on stomatal density and function.
The percentage increase in calculated values of IWUE ranges from ca. 24% for oaks from NORD to ca. 48% for beech from BEDS, with most of the increase occurring since 1930. These values are comparable to the 30% increase in IWUE from 1930s to 1980s reported for *Abies alba* in eastern France (Bert et al., 1997). The value for beech from BEDS (ca. 48%) falls just outside the increases since 1900 reported for beech in north eastern France (23–44%) (Duquesnay et al., 1998). It should be noted that neither Bert et al. (1997) nor Duquesnay et al. (1998) make allowance for any changes in meteorological parameters over their periods of study, so we compare our calculated values of IWUE directly with theirs. The fact that beech shows a stronger IWUE response than the oak or pine may be due to the particularly drought-sensitive nature of this species, caused by a relatively shallow rooting depth. Our measured increases in IWUE are in the range of values predicted from theoretical models (Beerling, 1994; Thornley and Cannell, 1996). However, the increases in IWUE displayed by our oaks are significantly higher than would be predicted from the results obtained from growing *Q. robur* seedlings in CO₂ concentration of 350 and 700 µmol mol⁻¹ (Picon et al., 1996) even when a reduction of ~4–5 µmol mol⁻¹ is made to the overall increase in IWUE that may result from decreasing humidity in Norfolk and southwestern Finland. Our findings therefore support the caution expressed in scaling up results from growth chambers experiments to mature trees growing under natural conditions (Shugart et al., 1986; Ceulemans and Mousseau, 1994; Thornley and Cannell, 1996).

Although the trees in this study show an overall increase in IWUE as expected, graphs of IWUE plotted against *cₐ* (Fig. 3) show that the rate of increase in IWUE reduces at higher values of *cₐ*, indicating lower sensitivities to increasing levels of CO₂. Such behaviour at ambient values of *cₐ* is not a feature of current models. The reduction in response is most clearly marked in the oaks from BEDS; but even at the other two locations reduction in response to increasing CO₂ concentrations might be greater than is suggested by Fig. 3 if decreasing humidity is affecting IWUE as discussed above. Figs. 2a and c show that relative humidity has been falling at an increasing rate in recent years at the sites in southwestern Finland and particularly in Norfolk. As discussed above, this could increase the value of IWUE by around 4–5 µmol mol⁻¹ over the period of study, with most of it occurring in more recent years, precisely where we observe the decreasing trends in IWUE in Fig. 3.

The relative behaviour of the trees seems to depend upon local site conditions. This can be seen in the oaks from NORD and NORW. Although the dry and wet sites are only 3 km apart, and hence subject to the same macro-climatic conditions, the trees from the dry site show a lower response to increasing *cₐ* than the trees from the wet site. Such contrasting behaviour accords with growth chamber experiments (Picon et al., 1996) in which well watered oak seedlings increased their WUE more than twice as much as droughted seedlings as *cₐ*.
increased from 350 to 700 μmol mol⁻¹. The similarity in response of trees from BEDS and NORD may reflect the similarity in soil drainage at the two sites, in contrast with the wetter site at NORW. Oaks from FIND and FINW, however, seem to behave more similarly, with perhaps a lower sensitivity to increasing $c_a$ shown by trees at the wet site in this case. This suggests either that, despite differences in hydrology, water-stress is not significantly different between the two Finnish sites, or that water-stress is not the dominant limiting factor.

Higher IWUE can result from increasing $A$ or decreasing $g_w$ or a combination of these factors. It is not possible to estimate the balance of factors in our trees, although reported concurrent increases in $A$ and decreases in $g_w$ for $Q. robur$ grown under increasing $c_a$ (Beerling et al., 1996; Picon et al., 1997) suggest that both factors play a role and are inherently linked. The response of $g_w$ to increasing $c_a$, however, may vary with species and conditions of water stress at the leaf level. Heath (1998) reported that young oak consistently decreased the value of $g_w$ in elevated CO₂, whereas the response of beech depended on the leaf-to-air vapour pressure deficit, at high levels of which $g_w$ of beech was unchanged in conditions of elevated CO₂.

Fig. 4 shows values of $c_i$ calculated from Eq. (2). The trees in this study seem generally to be adopting a strategy of homeostatic maintenance of $c_i$ levels against increasing $c_a$, at least until the mid-1970s. This behaviour contrasts with evidence for the maintenance of constant $c_i/c_a$ in plants as $c_a$ rises (Morison, 1987; Farquhar and Sharkey, 1982; Morison, 1993) and for increasing values of $c_i$ from AD 1800 displayed by a selection of trees growing in western North America (Feng, 1998). Subtle differences are evident between species and sites. In particular, after the mid-1970s, oaks at NORD and BEDS show $c_i$ increasing to values above the average for that of previous decades; this occurs concurrently with levelling IWUE values. The behaviour of $c_i$ and IWUE over this period may be linked to the effect of carbon dioxide concentration on two processes in C₃ plants. One of these processes is the observed reduction in stomatal index and stomatal density, which reach lower limits in $Q. petraea$ (Kürschner et al., 1996) and $Q. robur$ (Beerling et al., 1996) respectively at $c_a$ values above ca. 340 μmol mol⁻¹. The other is the biphasic nature of the response of $A$ to increasing $c_a$ (von Caemmerer and Farquhar, 1981; Woodward et al., 1991): an initially linear increase in $A$ curves less steeply at higher values of $c_i$. The deviation from linearity occurs at $c_i$ values that depend upon conditions and species, but it has been observed at $c_i$ values as low as ca. 330 μmol mol⁻¹ (von Caemmerer and Farquhar, 1981).

Our results, supported by those of other researchers, suggest that trees in different localities may be respond-
our observations, Franscy and Farquhar (1982) reported the maintenance of $c_a$ values of Tasmanian trees from 1870 to 1970. The reasons for the differences in behaviour are almost certainly related to local external factors, particularly to the availability of moisture and nutrients (Shugart et al., 1986; Duqueseay et al., 1998). It seems, however, that trees world-wide are adapting to increasing levels of atmospheric CO$_2$ in different ways. The reduction in sensitivity of IWUE to increasing $c_a$ shown by most of the trees in this study may be related to the loss in climatic sensitivity of lateward relative densities in recent years reported by Briffa and co-workers (1998). Whether this reduction in the rate of increase of IWUE is merely a temporary phenomenon remains to be seen; but it could represent a saturation effect. Such an effect, at comparatively low values of $c_a$, is neither observed in growth chamber experiments nor predicted by current models, which predict a continuing rise in terrestrial carbon storage as a result of the combined effects of CO$_2$ fertilization and climate change as $c_a$ increases (Mellillo et al., 1996; Cao and Woodward, 1998). If a long-term or permanent reduction in sensitivity to atmospheric CO$_2$ is established for a significant proportion of trees in temperate regions, the degree of future terrestrial carbon storage will have been greatly overestimated.
