Mechanistic modelling of weak interlayers in flexible and semi-flexible road pavements: Part 2

M de Beer, J W Maina, F Netterberg

This paper (Part 2 of a two-part set of papers) discusses models and illustrates the adverse effects of weak layers, interlayers, laminations and/or weak interfaces in flexible and semi-flexible pavements, also incorporating lightly cemented layers. The modelling is based on mechanistic analyses for pavement design and evaluation. In Part 1, the effects of these relatively weak layers, interlayers, laminations and/or weak interfaces were discussed. It was shown that methodologies are available to detect and investigate the existence of these weak layers in cemented pavement layers. In Part 2, several cases of the above conditions for different road pavement types are discussed, with field examples. Mechanistic analyses were done on a typical hot mix asphalt (HMA), several cases of a cemented base pavement and a granular base pavement, with and without these weak layers and interface conditions to demonstrate their adverse effects. The analyses focus on the strain energy of distortion (SED) as a pavement response parameter to indicate the potential for structural damage expected within the pavement structure or layer. Generally, the higher the SED, the higher the potential damage in the pavement layer. SED shows some potential for quantifying the relative effects of these weak layers, interlayers, laminations and/or weak interfaces within flexible and semi-flexible pavements.

INTRODUCTION

Low-strength, weak layers, interlayers, laminations and/or weak interfaces in the upper layers, such as bases and/or subbases, of flexible and semi-flexible road pavements are specifically prohibited in most specifications, as was discussed in detail in Part 1 of this paper (Netterberg & De Beer 2012 – see page 32 of this edition). For detailed definitions of the weak layers etc, and their associated conditions, see Part 1. As discussed in Part 1, premature pavement distress in the form of rippling, arcuate slippage, pumping, cracking or shoving of the bituminous surfacing and shallow base failures of cemented base pavements are not rare in southern Africa (see Photos 1 to 11 in Part 1). It is therefore important to discuss these observations and associated conditions in more detail in order to improve the quality of road construction in southern Africa.

In particular, the aim of Part 2 is to discuss and quantify the adverse effects of weak layers, interlayers, laminations and/or weak interfaces in pavement layers. This is done by means of selected examples of full-scale testing with the heavy vehicle simulator (HVS), including the so-called traffic-associated “crushing failure” found in the top of lightly cemented base layers. The discussion further includes detailed mechanistic analyses of various types of road pavement and interlayer conditions, used (and proposed) here to study the adverse effects of such layers.

As indicated in Part 1, the presence of these layers and/or conditions at any depth in the structural layers of a flexible or semi-flexible pavement (but especially the upper base) can therefore be quantified, albeit on a relative basis.

FULL-SCALE HEAVY VEHICLE SIMULATOR (HVS) TESTS ON SELECTED PAVEMENTS WITH CEMENTED LAYERS

Equipment such as the HVS is very useful in identifying the modes of failure of full-scale pavement structures, as is indicated in the following sections.
Road P95/1: Bronkhorstspruit – cemented base shallow pavement and poor layer thickness control

Kleyn et al (1985) reported on one of the first HVS tests on a shallow but thin (< 100 mm) strongly cemented base pavement on Road P95/1. It was shown that the sensitivity of the pavement increased dramatically when the traffic loading was increased, with a further increase in the rate of deformation when the layers were in a wet state. The layerworks of this pavement were not ideal, as shown in Photo 12 (see Part 1). It is postulated here that, in addition to the fact that this pavement was of relatively strong but thin and therefore shallow design, the rather poor layerworks (with some weaker layers present) might have influenced the structural performance of this pavement. The former should be seen relative to the behaviour of deeper pavement structures incorporating cemented base/subbase layers, based on the rate of deformation, which was about 50 times lower than that of the shallow pavement above (Kleyn et al 1985, Table 3).

Road P30: Hornsnek – cemented base pavement, interlayer and pumping

Opperman (1984) and later Kleyn et al (1985) discussed the structural performance of a strongly cemented gravel base and subbase pavement (Road P30) at Hornsnek, outside of Pretoria. This pavement started pumping after six years in service, and an investigation in 1984 showed the presence of a weak interlayer, unbound and probably a result of poor construction according to Opperman (1984), and not a case of carbonation (for a definition of “deleterious” carbonation in cemented road layers, see Part 1). Photo 1 (see Part 1) indicates the pumping under normal trafficking at that time. In this case, there was a weak interlayer with a thickness of between 25 and 80 mm between the cemented base and subbase, 105 mm to 215 mm from the surface. Owing to its thickness, this weak interlayer was also identifiable with the dynamic cone penetrometer (DCP). During HVS testing in the wet state, severe pumping of fines occurred on the pavement surface from this weaker interlayer, as shown in Photo 16. The cemented base also “collapsed” on the cemented subbase after the weaker interlayer had been “removed” by pumping (Kleyn et al 1985, Figure 6). This created a “deeper” pavement structure, demonstrating a “re-balancing” of the pavement under the action of traffic loading, especially in the wetter state. However, this took place at the cost of a rougher pavement surface (maximum deformation > 20 mm within 750 000 standard 40 kN load repetitions in the wet state) (Opperman 1984, Figure 8) with an associated lower functional riding quality as shown in Photo 17. This situation could have been avoided if the weaker layer had not been present in the initial construction of this pavement.

Asphalt base pavements on lightly cemented base and subbase layers: KwaZulu-Natal

This phenomenon was also observed and modelled during HVS tests on flexible asphalt base pavements, incorporating lightly cemented (C3/C4) subbase layers in KwaZulu-Natal (De Beer 1985, Chapter 5). In a case study by De Beer (1985) with the HVS on Van Reenen’s Pass, it was found that the full thickness of a 150 mm upper cemented subbase of an asphalt base pavement was relatively weak and fully carbonated. This particular layer was constructed during snowfalls in 1981, which hampered the construction control on site. This caused a “sandwiched” type of pavement structure, in which this weaker layer dominated the structural fatigue failure of the rather stiff recycled asphalt base of this pavement, even in the dry state (see Photos 18 and 19). Again, this illustrates the adverse effect of a weak layer within the upper supporting pavement layers. In another study De Beer (1985) showed the effect of erosion in the wet state of a cemented Berea Red Sand upper subbase underneath an asphalt base. In this case, a weak layer was created outside the wheel path, between the upper subbase and the asphalt base. In order to avoid
Fully carbonated and relatively weak upper cementitious subbase layer directly underneath the recycled asphalt base layer, resulting in a “sandwich” structure of a weak upper subbase on the N3 at Van Reenen’s Pass (De Beer 1985).

In another case of a relatively strongly cemented base pavement in the Cape, near Stellenbosch and Somerset West, Jordaan (1988) found that weak interlayers developed within the cemented base after traffic loading with the HVS, and also found a second weak interlayer just beneath the surfacing. In addition, crack activity measurements by Rust (1987) complemented the analysis of the traffic-associated failure of this pavement. Photo 20 indicates severe pumping during the HVS test on this road section in the wet condition. In addition, the adverse effect of moisture in the upper layers (i.e. wet state) was also demonstrated here, in that the bearing capacity of this pavement was reduced from 8 million standard axles in the dry state to a mere 1.6 million standard axles in the wet state (Rust 1987). This is another illustration of the combined action of traffic loading and moisture on these pavements, with reported evidence of weak interlayers.

Discussion

The above examples (as well as those discussed in Part 1) illustrate the importance of the actual pavement situation in the field versus the pavement structure as designed, specifically the occurrence and effect of weak layers, interlayers, laminations and/or weak interfaces in actual pavement structures. It should also be noted that, once surface failure is initiated for whatever reason, accelerated pavement failure occurs. This, of course, is also a strong function of road roughness and associated vehicle suspension, and therefore of axle and tyre dynamics, as indicated by Lourens (1995) and also Steyn (2001). This situation is aggravated when the pavement is in a wet condition. In addition to the examples given above, this accelerated damage progression on various types of pavement has been adequately demonstrated and documented through many years of HVS testing and associated observations of pavement failures in South Africa (Maree 1982; Freeme et al 1987; Rust et al 1997; Du Plessis et al 2008).

To aid in pavement evaluation for the purposes of rehabilitation, Freeme (1983) and Freeme & De Beer (1983) published documents defining the structural behavioural states of different flexible and semi-flexible pavement types (by catalogue) to inform engineers about specific evaluation and rehabilitation design strategies (see also Jordaan 1988). These documents demonstrate that relatively weak layers between structural layers in a pavement are highly detrimental to the pavement’s structural performance, and become even more crucial in wet conditions, as was discussed above. During wet conditions, the pavement easily changes its structural behaviour into what is referred to as the “moisture accelerated distress” (MAD) state, as reported by De Beer & Horak (1987). In the next section the so-called “crushing failure” of cemented base pavements is discussed.

CRUSHING FAILURE MECHANISM FOUND FOR CEMENTED BASE PAVEMENTS

Effect of tyre–pavement contact stress and associated crushing failure mode of a cemented layer

Lightly cemented base/subbase layers may also suffer from traffic-associated “crushing failure”. This failure mode could result from a relatively weak upper portion in cemented bases, but could even occur in relatively dry conditions (De Beer 1990). This “weakness”...
in the layer is to be seen relative to the applied contact stress it needs to carry from especially truck tyres. In this paper, it is assumed that the tyre inflation pressure is equal to the vertical tyre contact stress. However, a multitude of studies have indicated that three-dimensional (3-D) tyre–pavement contact stresses are not simple, and special provision should ideally be made to incorporate these complex contact stresses into pavement design (De Beer et al. 1997, 1999, 2002, 2004; De Beer 2006, 2008). In these days of higher tyre inflation pressures (and hence tyre vertical contact stresses of up to 1 000 kPa or more), the importance of avoiding a relatively weak upper base is well illustrated by Equations 1 and 2 (also see Figure 2). Figure 2 and these equations show the empirical relationships found for tyre contact stress-associated crushing failure in terms of the “initiation” of crushing failure (Crush Initiation, \( N_{ci} \)), as well as “advanced” crushing failure (i.e. Advanced Crushing, \( N_{ca} \)) (De Beer 1989a, 1989b, 1990; De Beer et al. 1997, 1999).

Crush Initiation \( (N_{ci}) \)

\[
Crush \ Initiation \ (N_{ci}) = 10^{8.21 \times \left(1 - \frac{\sigma_t}{2.2 \times UCS_{50}}\right)}
\]

Advanced Crushing \( (N_{ca}) \)

\[
Advanced \ Crushing \ (N_{ca}) = 10^{9.20 \times \left(1 - \frac{\sigma_t}{2.2 \times UCS_{50}}\right)}
\]

Where:

- \( N_{ci} \) = initiation of average crushing life span (units in repetitions of tyre–pavement contact stress, \( \sigma_t \))
- \( N_{ca} \) = advanced average crushing life span (units in repetitions of tyre–pavement contact stress, \( \sigma_t \))
- \( \sigma_t \) = tyre contact stress (~ tyre inflation pressure in this paper) in kPa
- \( UCS_{50} \) = \textit{in situ} DCP-derived unconfined compressive strength (UCS) of the top 50 mm of base layer in kPa
- The probability for \( N_{ci} = 50\% \), \( R^2 = 0.89, n = 23 \) (De Beer 1990).

For example, Figure 2 indicates that about one pass of a tyre resulting in an average vertical contact stress of \( \sigma_t = 1 000 \) kPa on a cemented base layer would immediately initiate the crushing mode of failure \( (N_c) \) of the upper base (~ 50 to 75 mm) with a similar \textit{in situ} UCS\(_{50}\) strength. Further, a UCS\(_{50}\) of about 3 MPa would be needed for 1 million contact stress repetitions before initiation of crushing failure in the upper 50 to 75 mm. The crushing (or compression) failure, even in the dry state, of a cemented base layer, as was observed under HVS testing, is illustrated in Photos 21, 22 and 23. The existing C3 base strength

Figure 2 Crushing failure of pavements incorporating lightly cemented base layers (modified from De Beer 1990)

Photo 21 Crushing (dry condition) of a lightly cemented base layer as a direct result of HVS trafficking (De Beer 1990)

Photo 22 Signs of pumping from the cementitious base layer during a wet HVS test, after crushing in the dry state (De Beer 1990)
requirement of UCS = 1.5 MPa (strength in the field) should therefore be adequate to carry about 1 million contact stress repetitions at \( \sigma_t = 500 \) kPa, and approximately 10 000 stress repetitions at a tyre contact stress of \( \sigma_t = 1000 \) kPa. These relationships (Equations 1 and 2) were empirically derived from DCP tests at HVS sites (De Beer 1990).

Further, as stated in the original work on the crushing failure mode, the initiation of crushing in thinly sealed cemented base pavements almost corresponds to the fatigue life of the thin asphaltic surfacing seal (De Beer 1989a, 1990). Advanced crushing \( (N_{ca}) \) corresponds to approximately 10 mm of deterioration (downward displacement) in the top of the cemented base, which is a strong warning sign of a shallow failure that may need urgent maintenance.

As shown in Part 1, it is therefore concluded that the creation (or existence) of relatively weak (crushed) upper layers, interlayers, laminations and/or interfaces due to any cause should be avoided at all costs, even at the expense of other aspects such as the quality of the surface finish.

MECHANISTIC PAVEMENT ANALYSIS WITH AND WITHOUT INTERLAYER SLIP

It is generally accepted that weak layers, laminations and/or weak interfaces of any kind in the upper base layer, including compaction planes, are highly detrimental to the structural and functional performance of a pavement, as shown by their general prohibition in nearly all specifications. Indeed, it can be quantitatively shown on a relative basis, based on the mechanistic pavement analysis methodology, that relatively smooth interfaces (see Photos 6, 7 and 8 in Part 1, and 24 and 25 alongside) and relatively weak interlayers (see Photos 12, 13 and 15 in Part 1) are highly detrimental at any depth in the base layer, and even at depth such as between the base and subbase layers. This is largely due to a redistribution of stresses and strains (or energy) as a direct result of a degree of “imbalance” caused by these weaker layers and/or weak interface conditions (e.g. AUSTROADS 1998; De Beer 1985, Chapter 5; Romanoschi & Metcalf 2001a, 2001b; Nageim & Hakim 1999).

For the case of a weak interface, a simple analogy would be the improved elastic deflection characteristics obtained by gluing the laminations of a laminated timber beam. An extreme analogy, applicable also to horizontal sliding failure in the upper base, would be the difference between a glued and an unglued ream of paper. Both crushing failure of a weak upper base and

Photo 23 Final state of the lightly cemented base layer after HVS testing and crushing, in the wet state (De Beer 1990). Note the amount of material lost from the wheel path in centre of photo

Photo 24 Field cores from lightly cemented base layer – left core: solid; right core: weak interlayers

Photo 25 Signs of delamination (possible construction plane) in a lightly cemented layer (De Beer 1990)
sliding on interfaces between laminations or weak interfaces appear to have contributed to many “shallow” base failures of cemented bases in southern Africa, though both have not necessarily occurred at each failed site.

In the following section examples of various mechanistic analyses show the relative effects of interlayers (weak layers, laminations and/or weak interfaces), based on the theoretical interlayer slip models developed by Maina et al. (2007). The relative importance of a lamination or weak interface of thickness $t \sim 0$ versus relatively weak layers, or interlayers of a definite thickness $t > 0$ versus simple weakening of a layer under the action of trafficking, is discussed using the mechanistic approach.

Strain energy of distortion (SED) as pavement response parameter

According to Timoshenko & Goodier (1951), the quantity of strain energy stored per unit volume of the material can be used as a basis for determining the limiting stress at which failure occurs. For this to be applied to isotropic materials, it is important to separate this energy into two parts – one due to the change in volume and the other due to the distortion – and to consider only the second part in determining the strength. Whatever the stress system, failure occurs when the SED reaches a certain limit. The mechanistic analyses discussed in this paper focus on SED as a pavement response parameter in terms of its value as an indicator of potential damage in a pavement layer. Generally, the higher the SED value, the higher the potential for damage in the pavement layer. SED shows some potential for quantifying the relative effect of these deleterious layers/conditions of interlayers in flexible and semi-flexible pavements. Theoretically, according to Timoshenko & Goodier (1951), the total strain energy per unit volume, $V_0$, is expressed by Hooke’s law, as follows:

$$V_0 = \frac{1}{2E}(\sigma_x^2 + \sigma_y^2 + \sigma_z^2) - \frac{\nu}{E}(\sigma_x \sigma_y + \sigma_y \sigma_z + \sigma_z \sigma_x) + \frac{1}{2G}(\tau_{xy}^2 + \tau_{yz}^2 + \tau_{xz}^2)$$  \hspace{1cm} (3)

so that SED can then be expressed as follows:

$$\text{SED} = V_0 - \frac{1 - 2\nu}{6E}(\sigma_x^2 + \sigma_y^2 + \sigma_z^2)^2$$  \hspace{1cm} (4)

Where:

- $E$ = Young’s Modulus (MPa)
- $\nu$ = Poisson’s Ratio
- $G$ = shear modulus (MPa)
- $\sigma$ = compressive or tensile stress (MPa)
- $\tau$ = shear stress (MPa)

Using Equations 3 and 4 it is anticipated that locations within the pavement structural layers that have relatively higher values of SED (i.e. so-called “hot spots”) will potentially fail first before points with relatively lower SED values. Note that the unit of SED is N-m/m³.

Example 1:

Pavement type: hot mix asphalt (HMA) base: smooth vs rough interface between top of subbase and bottom of asphalt base – vertical tyre loading only

In this section, an example of a lamination or interface (modelled as “smooth” or “full slip”) at the bottom of a typical HMA base airport pavement is demonstrated, relative to the case of full-friction (modelled as “rough” or “no slip”) condition by way of mechanistic modelling. Figure 3 shows an evaluation of interlayer slip conditions, i.e. a weak interface, which is modelled as a layer (or boundary condition) without any thickness, $t = 0$, for a typical flexible airport pavement structure (Maina et al. 2007). For the purpose of this paper, the results of utilising “Slip Model 3” (Equation 13 in Maina et al. 2007) are given since it seems to be more appropriate than other slip models investigated by Maina et al. 2007. The variation of SED with depth under the front outermost tyre of a Boeing 747-400 gear (of 16 tyres) (after Maina et al. 2007) for three slip rate values (indicating the percentage of horizontal movement allowed theoretically) is clearly
shown in Figure 3. The trend of maximum SED indicates that, whatever the slip rate value, relatively higher SED values are found at the surface of the pavement structure. Note that a slip rate of 0.0 represents “full friction” (no slip or full bonding) between subsequent horizontal layers, and a slip rate of 0.9 represents “full slip” (almost no friction or no bonding for practical purposes).

Figure 3 shows that as the slip rate increases, SED at the bottom of the top layer (where the interface slip occurs) increases to almost 75% of the SED obtained at the top of the pavement layer and this may result in a potential “bottom-up” failure condition.

Based on the SED analysis, interlayer slip may therefore influence the position and type of potential asphalt layer failures, such as cracking and deformation. Less drastic changes in SED occurred at the bottom of layer 2 as a direct result of the “re-balancing” of the stress and strain distribution within the pavement layers. The effect of this re-balancing is that the potential for distortion (i.e. SED) is shifted to the top layers above the lamination, interface or relatively weaker interlayer.

The general trend in SED with depth in Figure 3 is that, as the slip rate increases, SED tends to decrease through the thickness of the layer up to a certain depth within the asphalt base (in this particular case at a depth of approximately 30 mm), and then starts increasing again towards the bottom of the layer. In summary therefore, damage is expected to occur on the road surface (most probably rutting), as well as from the bottom of the asphalt base (most probably dominated by fatigue cracking, not excluding rutting from the bottom). This theoretical finding, however, needs further field verification.

Example 2:
Pavement type: cemented base: smooth vs rough single interface within the cemented base – vertical tyre loading only

In this section an example of a single laminating or weak interface (“smooth” boundary condition, also referred to as “full slip” or “no friction”) at a depth of L = 65 mm (i.e. 15 mm + 50 mm) in the cemented base (Road Category B, ES3, TRH 4 dated 1996, see COLTO 1996) is demonstrated. Slip Model 3 from Maina et al (2007) was also used for this analysis and the engineering model parameters are given in Table 1. As already indicated, the design capacity of this pavement is ES3 = 3 million standard axles (MISA) over 15 years. Note that MISA = million repetitions of a standard 80 kN axle with four tyres at 520 kPa tyre pressure, as defined in TRH 4 (COLTO 1996).

The load configuration is the standard loading per tyre, which is 20 kN and a value of 520 kPa for the contact stress. The layout of the pavement and its tyre loading used in the mechanistic analysis is illustrated in Figure 4. This figure also shows the different layer thicknesses and the depth of the lamination in the cemented base layer, which was modelled at a depth of L = 65 mm (i.e. 15 mm + 50 mm).

For the purposes of illustration, only one phase (i.e. the initial “pre-cracked” phase) of the structural behaviour of cemented layers is used here (for the different phases in the “life” of a cemented layer, see Theyse et al 1996). The SED results with vertical loading (V) only, under one tyre (Figure 4, Position A) and between the dual tyres (Figure 4, Position B) for this pavement condition are illustrated in Figure 5. Note that the various mechanistic analyses were done at two different positions, i.e. under the tyre (Figure 4, Position A) and between two tyres (Figure 4, Position B), and the SED values are reported through the depth of the pavement. Note that the case of vertical tyre loading (V) only, is considered in Figure 5.

The highest relative SED value of approximately 130 N-m/m³ (see red-dot curve) occurs at a position directly underneath the tyres at the depth (L) of the lamination (or weak interface), which is at L = 65 mm, from the surface of the pavement. The position of the second highest SED value (~ 28 N-m/m³, see

Figure 5 Strain energy of distortion (SED) results of the cemented case pavement. Note the relatively high value of SED at L = 65 mm with full slip (~ single lamination at L = 65 mm) directly under the tyre.

Figure 6 Strain energy of distortion (SED) results of the cemented base pavement for vertical load (V) only. Note the relatively high value of SED at L = 65 mm with full slip (~ single lamination at L = 65 mm) and relatively weak layer (t = 50 mm) on top of the base layer, directly under the tyre.

purple curve) was found to be at a position between the dual tyres (Figure 4, Position B), also at the depth of the lamination or weaker interface at L = 65 mm. Most of the other SED values are less than about 25 N·m/m³. Note that the higher SED values are concentrated in the top 65 mm of the pavement within the base layer, including a relatively weak layer (t = 50 mm) on top of the base layer, as indicated in Figure 5 (blue and green curves). In this case, the maximum SED of approximately 25 N·m/m³ is at a depth of 140 mm – at the bottom of the C3 layer (green curve).

It is therefore concluded that the SED of a cemented base layer with "full slip" (lamination or weak interface) peaks directly underneath the tyres (Position A) and is approximately 24 times higher than the case of full-friction (i.e. "no slip" or "rough" or "full bond") condition. This is an analytical demonstration of the potential adverse effect of a lamination or weak interface within the cemented base layer at this depth, as modelled here with SED. This unfavourable condition should be avoided at all times, as it is postulated that it will lead directly to premature fatigue failure in the top part of the cemented base pavement. It is probably also associated with the crushing failure of the top ~ 50 mm (discussed above) and hence with potholing in wet conditions. See Photos 3, 5, 6, 9, 11 and 15 in Part 1, and 21, 23, 24 and 25 in this paper (Part 2).

Example 3: Pavement type: cemented base: smooth vs rough single interface within the cemented base, including a relatively weak interface – vertical tyre loading only

In this example, Figure 6 illustrates the SED results of the same cemented base layer pavement discussed above, but including a relatively weak layer of 50 mm thickness (t = 50 mm) in the top part of the base layer. This condition is modelled with and without a lamination (or weak interface) at the bottom of this weak layer, with depth L = 65 mm. Again, for demonstration purposes only, vertical tyre loading (V) is considered here.

Compared with the results shown in Figure 5, the effect of adding a 50 mm relatively weak layer (modelled here as a layer of relatively low effective elastic modulus of 30 MPa) is quite dramatic. In this case, the maximum SED increased to a value close to 3 500 N·m/m³, which is approximately 30 times larger (Figure 6) than the case of lamination (full-slip weak interface) only, as shown in Figure 5.

The dramatic 30-fold increase in SED caused by this 50 mm weak layer clearly illustrates the higher potential for distortion (fatigue, rutting or further crushing) that may occur in the top 65 mm of this cemented layer. This, of course, could lead to premature failure, even during the construction period, if such a condition exists. Note also that most of the SED is concentrated in the top part of the cemented base (under the tyres, Position A) where the lamination, weak interface and weak layer are situated. This is also in sharp contrast to the ideal case of full friction and no weak layer within the base as indicated in Figure 5 (green curve), with maximum SED ~ 5 N·m/m² at 65 mm.

Example 4: Effect of horizontal (H) loading – position between the dual tyres (Position B in Figure 4)

To simulate the additional effect of turning/scuffing of tyres around sharp corners or curves, dual tyres with both vertical (V)
No Slip vs Full Slip – Between Tyres – with and without horizontal load (H) – Position B

No Slip vs Full Slip – Under Tyres – with and without Horizontal Load (H) – Position A

Figure 7 Strain energy of distortion (SED) results of the cemented base pavement midway between the two tyres, with and without horizontal (H) loading. Note the relatively high value of SED at 65 mm with full slip (~ single lamination at L = 65 mm) and the increase in SED on the surface when H-Load is considered under the tyres in addition to vertical (V-Load) only loading and with and without horizontal (H) loading in the same direction under both tyres, are considered. For demonstration purposes, H was assumed to be about 0.5 of V, i.e. H = 0.5 V (Figure 4). So, with V = 20 kN and H = 10 kN, the pavement was re-analysed in this example. Figure 7 illustrates the effect of SED for the given loading conditions at a position between the dual tyres (Figure 4, Position B), and represents a case where no slip ("rough") and full slip (i.e. lamination or weak interface) are considered. Although the SEDs obtained are relatively low for the "no slip" case (yellow and dark blue curves), the effect of SED can be seen within the cemented base layer, peaking at the top and bottom of the layer. Also note the increased SED within the cemented base with the horizontal load (compare the yellow and dark blue curves) between the depths of approximately 15 and 140 mm in Figure 7, suggesting some additional distortion energies within the cemented base layer under conditions of horizontal loading between the two tyre loadings. This is a direct result of the horizontal loading under the tyres, which has a potentially adverse effect (increased SED and therefore potentially increased damage) midway between the tyres for the case of no slip (or full friction).

As before, in the case of lamination or a weak interface (full slip) at L = 65 mm, SED peaks at this depth, but with a much-reduced SED of approximately 28 N-m/m³ (light blue and red curves), compared with the case under the tyres where the SED was approximately 130 N-m/m³, shown by the red curve in Figure 5. It is interesting to note that at this depth and position midway between the tyres (Position B, Figure 4) the additional effect on SED from horizontal loading seems to be relatively small (compare red and light blue curves in Figure 7).

Example 5:
Effect of horizontal (H) loading – position directly under tyres (Position A in Figure 4)

Figure 8 illustrates the SED results under one of the dual tyres (Position A). Here the peak SED value is also at the depth of lamination or full slip at L = 65 mm, as before, and is approximately 130 N-m/m³ for vertical loading only. This value increases to approximately 147 N-m/m³ if horizontal loading is also included. Note further the increased SED on the surface of the pavement, directly under the tyres, from a value of less than 5 N-m/m³ to approximately 100 N-m/m³, if horizontal loads are included. This suggests the relatively high potential for additional failure potential in the top 65 mm layer under conditions of turning (i.e. "scuffing"), acceleration or deceleration of the tyres on the surface of the pavement. This again shows that a condition of slip in the cemented base layer is to be avoided and, as discussed in Part I, this should be assured through proper inspection during construction and suitable repairs before these cemented base layers are sealed.

In Figure 9 the same situation as in Figure 6 (pavement with lamination together with a 50 mm weak layer) is considered, but with the additional horizontal (H) loading included in the analysis. Note the relatively small increase in SEDs compared with those given in Figure 6 for all cases investigated here. Based on the foregoing, it seems that the weak layer in itself overshadows the effect of additional horizontal loading under the tyres in this example. Again, the SED is concentrated in the top part (top 65 mm) of the pavement as modelled here, suggesting shallow failure potential from the top of the layer.
and L = 140 mm, together with a weak layer in the same base layer) at depths L = 65 mm
layer (i.e. two laminations or weak interfaces
In this example, the effects of a double slip
layer in depth – vertical tyre load only

Example 6: Pavement type: cemented base;
double slip interfaces – smooth vs rough interfaces within the cemented base, including a relatively weak layer in depth – vertical tyre load only
In this example, the effects of a double slip layer (i.e. two laminations or weak interfaces in the same base layer) at depths L = 65 mm and L = 140 mm, together with a weak layer (due to poor construction, and/or chemical breakdown) between depths of 65 and 140 mm are investigated under vertical tyre loading (V) only. The results are illustrated in Figure 10, which shows the maximum SEDs peaking at the depths of the laminations, i.e. L = 65 mm and L = 140 mm under the tyres (Position A). It is also clear that from a depth of 65 mm, SED increases largely due to the effect of the weak layer, in addition to the two slip layers (compare red and yellow curves with purple and blue curves). However, the resulting maximum SEDs under combined conditions of laminations

Example 7: Pavement: granular base on cemented subbases – with and without weak layer and/or slip
In this final example, a relatively strong pavement with a typical high-quality granular (G1 material (COLTO 1996) base layer supported by two lightly cemented layers is investigated. The layout of the pavement and its tyre loading used in the mechanistic analysis are shown in Figure 11. The objective here is to illustrate the effect of a 20 mm relatively weak layer in the top of the upper part of the cemented subbase supporting the G1 base layer by way of analysing the associated SED patterns. First, the pavement was analysed without any weak layer (i.e. solid C3 subbase). The results indicate a peak in SED ~ 100 N-m/m³ towards the middle of the G1 base layer at a depth of approx. 60 mm (blue curve in Figure 12). However, when a 20 mm weak layer is introduced directly underneath the G1 base layer, the SED increases greatly at the bottom of the G1 base layer, as well as within the 20 mm weaker layer (purple curve in Figure 12).
From experience, owing to pavement “strength balancing” under the action of tyre loading (or traffic moulding), the G1 granular layer will start to de-densify (or deteriorate) to a relatively lower quality and therefore become a less dense granular layer. This case is modelled here by a reduced effective elastic modulus of 200 MPa (changed from the original 500 MPa (~ G1)), representing a “weakened” G1 granular layer for illustration purposes. The 20 mm weak layer at the top of the upper cemented subbase (C3) is represented here by a weak interlayer (due to poor construction or deleterious chemical breakdown), modelled with an effective elastic modulus of 30 MPa. When the weak layer on top of the subbase, together with this “weakened” G1 base layer, is analysed, the SEDs in the granular...
SUMMARY, CONCLUSIONS AND RECOMMENDATIONS

In this paper (Part 2 of the two-part set) it was shown that modelling of flexible and semi-rigid pavements, including weak interlayers, laminations and/or weak interfaces, by way of mechanistic analysis using strain energies of distortion (SED) is quite insightful. In addition, experience and HVS testing have shown that the presence of relatively weak interlayers of any kind (i.e. laminations and/or interlayers of relatively weak quality) is far more deleterious to structural pavement performance than is commonly assumed. Especially the crushing mode of shallow failure and its quantification show good promise for the evaluation and prediction of the structural capacity of pavements incorporating lightly cemented layers under these adverse conditions.

It is concluded that the effects of weak interlayers, laminations and/or weak interfaces can be modelled mechanistically to illustrate and quantify potential failure conditions and their locations. The effect of potential crushing failure of cemented pavement base/subbase layers can also be quantified, albeit empirically. These conditions in the structural pavement layers should (and can) be avoided, especially during construction, in order to ensure quality structural performance of pavements of this nature in the long term.

For the design and modelling of durable flexible and semi-rigid pavements in the context of this paper, the following aspects are recommended:

- In medium to high-risk situations, the mechanistic methodology should include an analysis based on the SED parameter, which may greatly improve engineering understanding of the failure mechanisms, structural behaviour and associated potential for premature failure of flexible and semi-rigid pavements. This is
especially important in cases where the upper layers of these pavements may contain weak layers, interlayers, laminations and/or weak interfaces.

- Full-scale pavement studies should be performed and evaluated to calibrate the SED as a potential failure parameter, especially for roads in the conditions described above.

- Emphasis should be placed on ensuring that the construction quality of these pavements is maintained. If a relatively weak layer, interlayer, laminate and/or interface is indeed found in the upper layers of these pavement structures, it should be removed and rectified immediately before any further construction is done, as was discussed in Part 1.

Pavements incorporating cemented (stabilised) base layers should be evaluated for potential traffic-load-associated crushing failure related to higher tyre contact stresses as proposed in this paper. This is to avoid the shallow crushing failure of these layers when their strength is substandard relative to their strength specifications and the current demand of higher truck tyre contact stresses.
